J. Entomol, Sci. 38(2): 149-150 (April 2003)

The science of urban entomology has made great strides since 1935 when John J. Davis attended the Third Convention of Exterminators and Furnigators. Davis hat been credited with establishing the first visible liaison between professional entomology and the urban pest management profession. Ten years later, publication of the Handbook of Pest Control by Mallis set the tone for a generation of entomologists wit interest in the urban habitat. This relationship steadily gained momentum through the last half of the 20th Century as universities began adding urban entomologists to the faculties. At the dawn of this new century, the important role of urban entomology is achieving recognition because, for the first time in human existence, the world' population in urban areas exceeds that of rural areas.

Scheduled application of pesticides was, even 20 years ago, considered the mosefficacious form of urban insect pest management. Problems with pesticide exposure pest resistance, and pest resurgence are a few of the factors that have resulted i attempts to implement Integrated Pest Management (IPM) in the urban setting. IPI is a concept developed in agricultural entomology that has taken on many guise since conceptualized in the 1959 *Hilgardia* paper by Stem, Smith, van den Bosch an Hagen.

At the core of most definitions, IPM is the intelligent use of information on perbiology to implement interventions that limit pest populations. An intervention is defined as any action taken to reduce a pest population or, more importantly, the potential for pest population growth. In the urban setting, interventions include, but an not limited to, tactics such as habitat modification, sanitation, use of biological agent or pesticide applications. The need for intervention, termed the action threshold, decided by perceived, aesthetic, medical, or personal property damage caused to insect pests. Insect pest management interventions can be performed by builder landscape managers, architects, property owners, government agencies, or permanagement professionals to name a few of the diverse players who should to involved in urban IPM. The goal of Urban IPM should be sustainable reductions insect pest populations with minimal interventions.

Despite the appeal of sustainable and environmentally compatible insect pe management, implementation of IPM in the urban habitat has been slow. A variety reasons can be listed including: technical—lack of simple, effective monitoring d

ices and methods; public perception—the need to alleviate pest problems immeditely; conceptual—the lack of workable IPM models with reasonable action threshlds; economic—increased labor costs and lack of short-term profit; educational—ractitioner training and clientele information transfer and a lack of funding; and search—lack of interdisciplinary collaboration and funding. Ultimately adoption of PM in the urban setting should involve entomologists, medical professionals, economists, architects, builders, landscapers, property owners, and pest management prosessionals. Educating the practitioner and property owner that urban insect pest management is a process must be the foundation of this development. The scientific information gained in the last 40 yrs by urban entomologists should form the basis of lat educational effort. However, the liaison initiated over half a century ago by J. J. avis must be expanded to include all of the aforementioned professions. Only then an the development and implementation of IPM programs that are sound, financial interprises represented by value-added services and products become a reality.

The following 5 articles in this issue of *The Journal of Entomological Science* and which I address this introduction were part of a Symposium on IPM in Urban ntomology convened at the 2001 Entomological Society of America Annual Meeting San Diego, CA. The goal of this symposium was not to define or re-define Urban M but rather to provide information on research advances made in the past decade plative to selected Urban IPM programs. The presentations by leading U.S. ento-lologists focused on 5 of the major household and structural insect pest groups.

Although it has been argued that most urban insect pests can be categorized as casional invaders, A. G. Appel discussed how research on groups of minor ecoomic or medical importance and 'occasional pest' status offer opportunities to demastrate the feasibility of employing what should be the cornerstone of any Urban IPM ogram—habitat modification. Furthermore, the management of pest ants, historially, has been inconsistent and complicated by a myriad of concerns, not the least which is overcoming (or perhaps using) their social organization to assist in proding population reductions. Thus, M. K. Rust, D. A. Reierson and J. H. Klotz reewed the literature on Argentine ant control, concentrating on bait formulations as e best solution for an environmentally compatible approach. B. M. Drees and R. E. old discussed the development of fire ant control tactics and the success of areaide management programs using insecticidal baits while illuminating how current search efforts emphasize biological control. The final 2 papers published herein ldress the difficulties and advances in managing cryptic structural pests. V. R. wis's presentation of drywood termite control includes the topics of public percepn, detection technology, and legislative regulation of the industry as well as how ese factors may affect management options to the same degree as pest biology. istly, B. M. Kard discussed standard termiticide testing methodologies and adessed alternative treatments, such as stainless steel barriers, for subterranean rmite control.

It is our hope that the information contained in these papers will stimulate an terdisciplinary dialog toward development and implementation of practical Urban M.
